Abstract

We use a 3-D finite difference numerical model to generate synthetic seismograms from a simple fractured reservoir containing evenly-spaced, discrete, vertical fracture zones. The fracture zones are represented using a single column of anisotropic grid points. In our experiments, we vary the spacing of the fracture zones from 10-meters to 100-meters, corresponding to fracture density values from 0.1- to 0.01-fractures/meter, respectively. The vertical component of velocity is analyzed using integrated amplitude and spectral attributes that focus on time windows around the base reservoir reflection and the scattered wave coda after the base reservoir reflection. Results from a common shot gather show that when the fracture zones are spaced greater than about a quarter wavelength of a P-wave in the reservoir we see 1) significant loss of amplitude and coherence in the base reservoir reflection and 2) a large increase in bulk scattered energy. Wavenumber spectra for integrated amplitude versus offset from the time window containing the base reservoir reflection show spectral peaks corresponding to the fracture density. Frequency versus wavenumber plots for receivers normal to the fractures separate backscattered events that correspond to spectral peaks with positive wavenumbers and relatively narrow frequency ranges. In general, backscattered events show an increase in peak frequency as fracture density is increased.

Title: Executive Director/Research Scientist – Earth Resources Laboratory

Acknowledgements

First and foremost, a special thank you to Daniel Burns for his guidance and support throughout the year as I gained confidence in a new topic. I would also like to thank Nafi Toksöz for his fruitful suggestions regarding my current as well as future work, Rama Rao for his technical support while I grappled with MATLAB, and Dale Morgan for his many constructive criticisms and philosophical discussions.

I would like to acknowledge the Rock Fracture group (Dan Burns, Mary Krasovec, Mark Willis, Burke Minsley, and Joongmoo Byun) for many helpful comments and exposure to different aspects of the fracture problem during our weekly meetings. In particular, I would like to thank Joongmoo Byun for his invaluable computing efforts.

I am grateful to newfound friends, Joe Shuga, Mauro Brigante, Alejandro Dominguez Garcia, and Katerina Spyropoulou, as well as many old friends who kept my spirits high when I was feeling low. Last but not least, I would like to thank my family and especially my parents for all the love and support they have given me for as long as I can remember.

This work was supported by the Earth Resources Laboratory Founding Members, the Department of Energy grant number DE-FC26-02NT15346, and by ENI S.p.A. AGIP.

1. Introduction

Fractures are common within the subsurface and play a critical role in the mechanical and fluid flow properties of earth materials. In regions where the maximum compressive stress is vertical, open fractures will tend to be oriented vertically. The ability to interpret properties such as fracture spacing, orientation, and fluid content associated with such fracture systems is vital to the effective extraction and management of reservoir resources and the monitoring of contaminant migration. In particular, the ability to delineate zones of high fracture density is a key component in developing reservoir-scale fluid flow models.

The way in which fractures affect seismic waves depends on mechanical parameters, such as compliance and saturating fluid, and on their geometric properties, such as dimensions and spacing. When fractures are small relative to the wavelength of the seismic waves, the waves will be only weakly affected by the fractures. If fractures have characteristic lengths on the order of the wavelength then there will be scattering of energy due to the presence of the fractures. Similarly, fractures spaced much closer than the wavelength of the seismic waves are not individually sampled and result in a homogeneous, anisotropic medium. When fractures are spaced further away (about a quarter of a wavelength or more) the seismic waves will interact with the fractures and scatter appreciable energy.

Observations by previous researchers have demonstrated that scattering effects are sensitive to fracture density in real data as well as numerical and laboratory experiments (Ata and Michelena, 1995 and Rathore et al., 1994). In addition, numerical modeling of fractured media has proven to be an efficient way to explore the feasibility of using seismic waves to estimate fracture parameters. In particular, the applicability of finite difference methods to simulate wave propagation in a fractured elastic medium has been well documented in the

literature (Shen and Toksoz, 2000, Daley et al. 2002, Nihei et al., 2002, Wu et al. 2002, Groenenboom and Falk, 1999, and Nakagawa et al. 2002).

Most previous work in estimating fracture parameters from seismic reflection data has focused on using an equivalent medium approach where the fractures themselves or the spacing between the fractures is assumed to be small relative to the wavelength of the seismic wave. In this paper, we explore the characteristics of reflected and scattered elastic waves that may be used to develop seismic attributes sensitive to fracture spacing. A 3D finite difference method is used to simulate wave propagation through a simple fractured reservoir which is modeled as a single horizontal layer containing parallel, evenly-spaced fractures. Previous work has shown that the finite difference method is accurate over a wide range of scattering regimes and can account for all converted waves and their interactions (Shen et al., 2002). Synthetic seismograms are generated along transects perpendicular and parallel to the fracture orientation and we analyze spectral characteristics of the wavefield scattered from the fracture zones. Our objective is to investigate how the intensity of seismic scattering changes with the spacing of discrete fractures, and develop potentially diagnostic seismic attributes sensitive to the fracture spacing. Our analysis focuses on the P-wave reflection from the bottom of the reservoir and the coda waves that follow the primary reflections.

2. Background

The importance of fractures in the production and stimulation of reservoirs has resulted in considerable efforts to develop methods for fracture detection and characterization using seismic waves. In particular, offset dependent attributes are useful in characterizing vertical fractures because of the variation in incidence angle of waves impinging on the fractures.

2.1 Equivalent Medium

Much effort has focused on measuring amplitude variations with offset (AVO) for seismic reflections from a fractured reservoir (Gray et al., 2002, Perez et al., 1999, and Shen et al., 2002). Amplitude variation with offset and azimuth (AVOA) has been widely used to identify the orientation of vertical fractures with variable levels of success (Ruger, 1998; Mallick et al., 1998; Perez et al., 1999; Shen and Toksoz, 2000; Minsley et al., 2003). In these applications, the fractures are assumed to be small relative to the wavelength of the seismic waves. This allows the fractured medium to be modeled using an equivalent anisotropic medium (Schoenberg and Douma, 1988). Others have looked at shear wave data for fracture analysis (Lynn et al., 1995; Gaiser et al., 2002).

Shen et al. (2002) used numerical experiments and field data from a fractured reservoir in Venezuela to demonstrate the advantages of using attributes based on frequency variations with offset and azimuth (FVOA) in addition to AVOA based attributes to further constrain the interpretation of parameters related to the presence of vertically aligned fractures.

2.2 Discrete Fracture Zones

Recently, researchers have begun to focus on relaxing the assumption of relatively small fracture spacing by incorporating the effects of discrete fractures. Shen and Toksoz (2000) used stochastic models to generate heterogeneous fracture density distributions. They examined the effect of such fracture density variations using both time-domain and frequency-domain attributes and found that the presence of the fractures was more easily identified in the attributes associated with the base reflector. They concluded that first-order effects of fractures on FVO and AVO were controlled by the mean fracture density used in their stochastic fracture representation; however, they did not investigate systematic variations in fracture spacing.

Daley et al. (2002) conducted finite difference modeling of discrete fracture zones aimed at identifying scattering mechanisms and resolvability issues. They concluded that fracture tip diffractions and P-to-S conversions are the dominant scattered events from discrete fracture zones observable in surface seismic data, and identified fracture stiffness, spacing, and spatial scale as important parameters in controlling the resolvability of discrete fracture zones. Although their fractured reservoir model is similar to the one used in this paper, they do not specifically address the development of scattering-based attributes sensitive to variations in fracture density.

Nakagawa et al. (2002) developed a hybrid numerical method that combines the plane wave method and the finite element method in order to examine the characteristics of the scattered wavefield from a layer containing discrete, vertical, evenly spaced fractures. However, their paper is more concerned with the presentation of the model and doesn't address variations in background velocities between fractured and unfractured layers or the fracture spacing.

3. Modeling

As discussed in the previous section, a great deal of research has focused on the applicability of finite difference methods to modeling seismic scattering phenomena. In particular, Nihei et al. (2002) test the performance of the Coates and Schoenberg (1995) equivalent medium anisotropic cell approach for FD modeling of discrete fractures. The finite difference method is advantageous when modeling the scattering effect of discrete fractures because of its stability over a wide range of material property contrasts and its ability to model all wave types with minimal numerical dispersion and anisotropy. In addition, synthetic

seismograms can be generated at any point within the model domain facilitating the simulation of surface seismic acquisition geometries.

3.1 Model Configuration

We use the time domain, staggered grid finite difference code developed by Lawrence Berkeley National Laboratory (Nihei et al., 2002), which solves the 3-D, anisotropic stress-velocity formulation of the elastic wave equation (Levander, 1988). This formulation accounts for geometric spreading but does not include intrinsic attenuation. The finite difference operator is 4th order accurate in space and 2nd order accurate in time. The model uses constant grid spacing in all directions of 5-m and a time step of .5-msec. For all model runs, the source is a Ricker wavelet with a center frequency of 40-Hz.

3.2 Model Geometry

Our numerical experiments use a simple reservoir geometry consisting of three horizontal layers. The first and third layers bound the reservoir and are homogeneous and isotropic with the same material properties. The second layer, which is 100-m thick, contains the fractures. Figure 1 shows the model geometry for a fracture density of .02-frac/m (i.e. 50-m fracture spacing) and the background velocities used for all model runs. Although absorbing boundary conditions are incorporated into the model, the boundaries are also placed far enough away so that any boundary reflections are not recorded in the seismograms during the time interval of interest.

The model uses a standard surface seismic reflection acquisition geometry, however, the source and receivers are embedded within the first layer to eliminate free surface effects. Receivers are placed in the crack normal and crack parallel directions with the first receiver fixed at the source. The receiver spacing is 20-m with the maximum source-receiver offset at 800-m which corresponds to a maximum angle of incidence of 45° relative to the top of the reservoir.

The fractures begin at a distance in the x-direction of 5-m from the edge of the grid and are then placed in even increments across the reservoir as dictated by the fracture density. The source is also fixed at a point above the reservoir corresponding to a distance in the x-direction of 550-m from the edge of the model domain. As a result, the actual locations of fractures relative to receivers are different for models with different fracture densities.

3.3 Fracture Representation

We incorporate discrete vertical fracture zones into the reservoir layer using a single column of anisotropic grid points. The elastic properties of the discrete fractures are calculated using the Coates and Schoenberg (1995) thin anisotropic grid cell approach. The fractures are assumed to have negligible mass and thickness relative to the seismic wavelength in accordance with the linear slip model of Schoenberg (1980) for imperfect interfaces. The fractures are given equal normal and tangential stiffness of 8×10^8 -Pa/m (Nihei et al., 2002). We assume fracture zones are bed terminated and have constant fracture density across the reservoir for each of our simulations.

4. Results

We generated synthetic data using the finite difference code and model geometry presented in the previous section. Given the source peak frequency of 40-Hz and the P- and S-wave velocities, the wavelengths in the reservoir are about 100-m and 60-m for P- and S-waves, respectively. Synthetic seismograms were produced for the no fracture case as well as for five different fracture density values: 0.01, 0.02, 0.0286, 0.04, and 0.1-frac/m (corresponding to fracture spacing values of 100, 50, 35, 25, and 10-m).

For the purposes of describing the model output, we will focus on two time windows of the time series. The first travel time window is bounded by the two coherent P-wave reflections and the second window contains all data after the estimated P-wave reflection from the base of the reservoir. We will focus on the vertical component of velocity for receiver arrays oriented normal and parallel to the fractures

4.1 Receiver Array Normal to Fractures

Figure 2 shows the vertical component of velocity recorded at each receiver position normal to the fractures for each fracture density case. The no fracture case is useful for identifying the main P- and S-wave reflections from the top and bottom of the reservoir. The first time window contains only the coherent P-wave reflections. However, careful observation shows a third event separates from the 2nd P-wave reflection at large offsets. The event is associated with the downgoing P-wave reflected as an S-wave at the base of the reservoir, and then converted back to a P-wave upon leaving the reservoir. Because of this conversion, the event has a slightly slower apparent velocity than the primary P-wave reflection from the base of the reservoir.

The dominant events in the second time window are the S-wave reflections, which show rapid increases in amplitude as offset increases because we are looking at only vertical particle velocities from our receivers. The S-wave reflection from the top of the reservoir has a relatively large amplitude while the S-wave from the base of the reservoir has a much smaller amplitude at least partially due to the additional conversions to P-waves as seen in the first time domain.

As we begin to incorporate fractures into the reservoir, we see a drastic change in the character of the time series. For the .01-fractures/meter case, the first time window shows the P-wave reflection from the top of the reservoir remains relatively unaffected while the P-wave

reflection from the base of the reservoir shows significant interference from scattered events starting at about 400-m offset. The apparent velocity of the second P-wave reflection decreases owing to the presence of the more compliant fractures.

In the second time window, we see that both S-wave reflections have become difficult to follow. The S-wave reflection from the top of the reservoir is affected by interference from scattered waves and shows better coherence at larger offsets where its amplitude is large. However, the S-wave reflection from the base of the reservoir is completely drowned out by scattering from the fractures. Overall, the second time window is dominated by many different events derived from interactions with the fractures. Close observation shows these events seem to focus at offsets between 200-m and 600-m and at travel times after the S-wave reflection from the top of the reservoir.

As we increase the fracture density to .02-fractures/meter, the same trends are observed. In the first time window, the P-wave reflection from the top of the reservoir shows an appreciable decrease in amplitude with offset. The P-wave reflection from the base of the reservoir becomes more incoherent at smaller offsets and is more difficult to follow from receiver to receiver. The decrease in amplitude of both P-wave reflections can be attributed to a combination of effects: a decrease in the impedance contrast between the two layers, reflected energy losses from interactions with the fractures, and to interference from scattered waves with relatively short travel paths.

In the second time window, the S-wave reflection from the top of the reservoir is only observable at very large offsets and the S-wave reflection from the base of the reservoir is absent. The scattered events have a very similar appearance to those for the .01-fractures/meter case except there doesn't seem to be a focus of scattered energy in the mid-offset receivers.

For the .0286-fractures/meter case, the first time window shows the P-wave reflection from the top of the reservoir is being interfered with at much smaller offsets (about 400-m). In addition, we observe a substantial increase in the amplitude of events not associated with the primary reflections at large offsets within the first time window. These observations suggest shorter travel paths and larger amplitudes for these scattered events.

The second time window contains a relatively large amplitude S-wave reflection from the top of the reservoir whose amplitude reaches a maximum between 400-m and 500-m offsets. In fact, scattered events tend to have larger amplitudes and arrive at earlier times than the previous cases. Again, these observations support shorter travel paths and larger amplitudes for scattered events.

The .04-fractures/meter case shows a sudden change in the character of the time series. In the first time window, the P-wave reflection from the top of the reservoir is still interfered with at larger offsets but the magnitude of the interference is smaller. The P-wave reflection from the base of the reservoir becomes much more coherent; however, it is now interfered with by an event that arrives at almost the same time even at zero offset and having a very similar move-out behavior. In general, we can now clearly observe that the apparent velocity of the P-wave reflection from the base of the reservoir has decreased substantially from the case with no fractures.

For the second time window, we see that the S-wave reflection from the top of the reservoir is clear and its amplitude increases with offset. The amplitude of the scattered events has decreased substantially and there are patches within the time series where no noticeable scattered energy is present. However, the weak scattered events that remain show similar move-out trends to those observed in the previous fracture density cases.

In the .1-fractures/meter case, we see almost the same behavior as the no fracture case. In the first time window, we only observe the P-wave reflections from the top and bottom of the reservoir. The amplitude of the P-wave from the top of the reservoir decreases more rapidly with offset than the no fracture case. The move-out velocity of the P-wave reflection from the bottom of the reservoir is much smaller. In the second time window, the S-wave reflection from the top of the reservoir is larger in amplitude. Almost no scattered energy is present within either time window. These observations are consistent with the equivalent medium representation that is applicable when fracture spacing is much smaller than the wavelength of the seismic waves.

4.2 Receiver Array Parallel to Fractures

The vertical component of velocity for receivers parallel to the fractures can be observed for each fracture density case in Figure 3. As we expect, the no fracture case has identical time series data as obtained from receivers in the normal direction. For the .01-fractures/meter case, we observe very little change in the first time window. Both P-wave reflections are coherent and the apparent velocity of the P-wave reflection from the base of the reservoir is slightly slower than the no fracture case.

For the second time window, the S-wave reflection from the top of the reservoir is observable at only large offsets. The scattered events are much more coherent from receiver to receiver and seem to have move-out trends similar to the P-wave reflections. In addition, the scattered events have smaller amplitudes than those obtained from the receivers normal to the fractures.

The .02-fracture/meter case shows similar trends to the .01-fractures-meter case. The P-wave reflection from the top of the reservoir is coherent across all offsets. However, the P-wave reflection from the base of the reservoir is difficult to follow at large offsets and has significant

interference from scattered events at small offsets. The S-wave reflection from the top of the reservoir can only be observed at large offsets. Again, we see that the scattered events have move-out trends similar to the P-wave reflections.

For the .0286-fractures/meter case, we again see that the P-wave reflection from the top of the reservoir is unaffected. However, the P-wave reflection from the base of the reservoir loses coherence at an offset of about 400-m. The S-wave reflections can not be distinguished; however, there is a focusing of large amplitude scattered energy around the time interval of the S-wave reflections. In general, this scattered energy has a similar move-out trend but is more concentrated particularly at small offsets.

In the .04-fractures/meter case, both P-wave reflections are very coherent and there is little scattered energy present. In general the .04-fractures/meter case is similar to the .1-fractures/meter case with a couple of exceptions. The .04-fractures/meter case has some small interference of the P-wave reflection from the base of the reservoir as compared to the .1-fractures/meter case. Also, the .04-fractures/meter case has enough residual scattered energy to blur the S-wave reflection from the base of the reservoir while this event is clear in the .1-fractures/meter case.

4.3 Snapshots

Snapshots of the wavefield in the presence of discrete fracture zones highlight the different scattering events and their interactions. Figure 4 shows the vertical component of velocity after .45-seconds for a fracture density of .02-fractures/meter. We see that the P-wave reflection from the top of the reservoir remains relatively coherent, while the P-wave reflection from the base of the reservoir is much more effected by the presence of the discrete fractures. This figure also illustrates the difference in coherence of the scattered wavefield normal and

parallel to the fractures. Normal to the fractures, interference of scattered waves from the fractures results in a complex wavefield (Figure 4a). Fractures act as secondary sources with observable forward and backscattering as well as multiple scattering events. Parallel to the fractures the wavefield is much more coherent and the fractures appear to act as waveguides (Figure 4b).

5. Analysis

The purpose of this section is to present seismic attributes developed to quantify the effect of variations in fracture density in our models.

5.1 Velocity Anisotropy

In general, aligned fractures will result in velocity anisotropy, which is often used as a measure of fracture intensity. Therefore, we examined the effect of variable fracture density on the normal move-out (NMO) velocity estimated by following the P-wave reflections as a function of offset (note: although our models are generated for a single source position with multiple receivers, and therefore are common shot gathers, we treat them as if they were a CMP gather). In our simple model, the NMO velocity of the upper layer will simply be the P-wave velocity specified for the upper layer, 3000-m/s. However, energy reflecting from the base of the reservoir will pass through both layers and potentially fractures as well. Therefore, the NMO velocity of the P-wave reflection from the base of the reservoir should depend on the fracture density and this effect should be strongest when measured normal to the fractures.

To estimate the NMO velocity, we pick the closest peak in amplitude associated with the P-wave reflection from the base of the reservoir at every offset and use the hyperbolic move-out equation to fit the time values of these peaks using a linear least squares regression. Figure 5a

shows the best-fit velocity curve for the .02-fractures/meter case and shows appreciable variation in the peak amplitudes about the best-fit model.

Using this approach, we calculated NMO velocities parallel and perpendicular to the fractures for each fracture density case (Figure 5b). In the parallel direction, the NMO velocities remain relatively constant although slight variations exist at fracture density values between .01-fractures/meter and .0286-fractures/meter. Conversely, the NMO velocities in the normal direction decrease as the fracture density increases and again we see irregular fluctuations in NMO velocity for the fracture density values between .01-fractures/meter and .0286-fractures/meter.

As we pointed out in the previous section, the presence of discrete fractures in our model affects the coherence of the P-wave reflections because of interference from scattered events. Therefore, as our observations indicate, we expect to see the greatest variability in NMO velocity for fracture density values associated with the greatest amount of scattering. This is important because using velocity anisotropy alone to estimate the fracture density associated with large discrete fractures may lead to erroneous results.

5.2 Bulk Scattering

In addition to velocity anisotropy, it is also important to quantify the amount of scattering present in the different fracture density cases. To calculate the amount of scattered energy in each time series output, we select a time window that incorporates as much of the data as possible while giving an equal time duration for each receiver (Figure 5c). We then take the absolute value of the windowed amplitudes and sum them to get a single integrated amplitude value. This procedure is done for the normal and parallel directions and for each fracture density value.

Figure 5d shows the resulting integrated amplitude values as a function of fracture density and orientation. The shapes of the integrated amplitude curves are nearly identical in the normal and parallel case. However, the normal case has much larger integrated amplitude values in the fracture density range between .01-fractures/meter and .0286-fractures/meter. The integrated amplitude values rise sharply as you move away from the no fracture case, reach a peak at the .0286-fractures/meter case, and decline more gradually towards the .1-fractures/meter case. The fracture density of .0286-fractures/meter obtains a value almost three times that of the case with no fractures in the normal direction. The .1-fractures/meter case falls to the no fracture case in the normal direction and actually falls below the no fracture case in the parallel direction, due to a change in AVO response.

5.3 1D Spectra of Integrated Amplitude versus Offset

We have demonstrated that the strongest scattering of seismic energy occurs for the fracture cases between .01-fractures/meter and .0286-fractures/meter. Now we will extend the integrated amplitude approach to develop an offset dependent attribute sensitive to fracture spacing within this strong scattering regime. We will focus on the P-wave reflection from the base of the reservoir and construct a robust window to capture this event and scattered events with similar arrival times. As we have shown, the P-wave reflection from the base of the reservoir is difficult to follow because of interference from scattered events. For this reason, we use a relatively large window based upon the NMO velocity of the P-wave reflection from the top of the reservoir. However, the P-wave reflection from the top of the reservoir does not sample the fractures directly and so will be excluded from the window. The same window is used for all fracture density cases making it robust in its application. Amplitude values within

the window are rectified and then summed to give a single integrated amplitude value for each offset.

Figure 6 shows the plots of integrated amplitude versus offset for each of the fracture density values with receivers normal to the fractures. In the absence of strong scattering, as in the no fracture case, we see that the curves show a smooth line dominated by the AVO response of the P-wave reflection from the base of the reservoir along with secondary effects from P to S conversions as described in the Data section. For the fracture density range associated with strong scattering, we also observe an AVO trend in the integrated amplitudes with offset; however, there are also periodic fluctuations about the AVO trend. These fluctuations are the greatest for the .01-fractures/meter and .02-fractures/meter case and are substantially less in the .0286-fractures/meter case.

Figure 7 displays the same integrated amplitude versus offset plots parallel to the fractures. We see the same trends in these plots but they lack the oscillations about the AVO trend. The difference between the normal and parallel cases is consistent with our earlier observation that scattered events in the parallel case tend to have move-out trends similar to the primary reflections. Therefore, we conclude that the interference patterns observed in the integrated amplitude versus offset from the normal direction may have a direct correlation with fracture density.

To test this hypothesis, we transform the integrated amplitude versus offset data in Figure 6 to the wavenumber domain using the Fast Fourier Transform (FFT). Since the resulting spectra are dominated by the AVO trend in the data, we remove this trend by normalizing the spectra. If the method is to be robust, the fracture density estimate must be insensitive to the spectrum used to normalize. To address this issue, we normalize the spectrum obtained from

each of the strong scattering fracture density values (i.e. .01-, .02-, and .0286-fractures/meter) with each of the spectra obtained from the weak scattering regime (Figure 8). Several important observations can be made from the resulting normalized spectra:

- 1) Peaks in the normalized spectra correspond to the input fracture density values for the .01-fractures/meter and .02-fractures/meter cases.
- 2) The ability to resolve the .0286-fractures/meter spacing is beyond the resolution of the analysis, which is determined by the receiver spacing.
- 3) The method is robust with respect to the spectrum used to remove the dominant trend and gives accurate estimates even when the .04-fracture/meter spectrum is used.

5.4 2D Spectra of Time Series versus Offset

The previous analysis method focuses on the time window around the P-wave reflection from the base of the reservoir. However, we have demonstrated that a great deal of energy arrives much later than the P-wave reflections. Attempts at using the integrated amplitude method presented in the previous section for this second time window, resulted in erroneous estimates of the fracture density based on spectral peaks because of the potential superposition of many different scattered events.

To better understand the complexity present in this second time window, we use the 2D FFT to analyze the time series versus offset data. For each fracture case, the same window is applied that captures all the data following the first time window presented in Figures 6 & 7. The traces are zero padded to maintain the same absolute time for all traces. In addition, a cosine taper is applied to smooth the edges of the windowed data.

Figure 9 shows the results of the 2D FFT for each fracture density value when the receiver array is normal to the fractures. In the no fracture case, all of the spectral peaks in

amplitude are associated with negative wavenumbers. The peaks also have several distinguishable ridge-like structures whose slopes are in the range of the NMO velocities of the S-wave reflections from the top and bottom of the reservoir.

When we examine the high scattering cases, the spectral peaks now have both positive and negative wavenumbers and we lose the coherent ridge-like structures seen in the no fracture case. Of particular interest are the patterns in spectral peaks associated with the positive wavenumbers. These peaks are associated with events that are arriving across the receivers in the opposite direction of the reflections. The spectral peaks associated with positive wavenumbers also have narrow bandwidth. Therefore, we conclude that spectral peaks with positive wavenumbers are associated with backscattered events from the fractures.

We observe systematic changes in the nature of the backscattering as the fracture density changes. The .01-fractures/meter case seems to have multiple peaks with the largest peak at a wavenumber of $.01\text{-m}^{-1}$ and a frequency of about 40-Hz. Overall, the .01-fractures/meter case has four identifiable peaks that seem to have increasing frequency with increasing wavenumber.

The .02-fractures/meter case has the same spectral peak at a wavenumber of $.01\text{-m}^{-1}$ but lacks the other spectral peaks seen in the .01-fractures/meter case except for the peak at the largest frequency. The .0286-fractures/meter case shows a strong peak at a wavenumber of about $.014\text{-m}^{-1}$ with a frequency close to 60-Hz. The .04-fractures/meter case has a peak at a wavenumber of about $.018\text{-m}^{-1}$ with a frequency of about 70-Hz. Also, the negative wavenumber peaks for the .04-fractures/meter case seem to be showing more of the ridge-like structure observed in the no fracture case.

The .1-fractures/meter case has a very similar pattern to the no fracture case. There are no spectral peaks in the positive wavenumber domain. The negative wavenumber domain shows

ridge-like structure with velocities in the range of the S-wave reflections. However, the trend of these ridges is slightly different owing to the change in mechanical properties of the reservoir due to the presence of the fractures.

Figure 10 shows the results of the 2D FFT for each fracture density when the receiver array is parallel to the fractures. In all of the fracture cases, we observe no spectral peaks in the positive wavenumber domain. For the fracture density values from .01-fractures/meter to .04-fractures/meter, we see that the smooth, ridge-like structure has been significantly disrupted. In addition, close comparison between figures 9 & 10 shows that the spectral peaks in the positive wavenumber domain for the direction normal to the fractures can also be seen in the negative wavenumber domain for the direction parallel to the fractures. This observation is consistent with the fractures acting as secondary sources and scattering energy in all directions and this scattered energy having move-out trends in the parallel direction similar to the reflections.

6. Discussion and Conclusions

We used a finite difference code to model scattering from discrete, vertical fractures with constant fracture spacing across the domain. Observations from vertical velocity time series show that scattering along receiver transects normal to fractures contain more complex wave patterns while receiver transects parallel to fractures tend to only have hyperbolic move-outs similar to the primary P-wave reflections. This implies that, if fractures behave as scatterers, stacking data obtained normal to fractures may remove valuable information regarding fracture parameters while stacking data parallel to fractures may retain such information (Willis et al., 2003).

Analysis of NMO velocities associated with the P-wave reflection from the base of the reservoir show that using velocity anisotropy to estimate fracture intensity might lead to erroneous results when fractures strongly scatter seismic waves. For our numerical experiment, this strong scattering regime occurs between fracture densities of .01-fractures/meter and .0286-fractures/meter. Given the background velocities in our reservoir, this strong scattering regime dominates when fracture spacing is greater than about a quarter wavelength of a P-wave in the reservoir. This observation agrees with well-established theory on scattering of waves by heterogeneities (Aki & Richards, 2002).

We use a robust window about the P-wave reflection from the base of the reservoir to calculate integrated amplitude values as a function of offset. When receivers are normal to the fractures, we observe periodic fluctuations about the general AVO trend within the strong scattering regime. Transforming this information to the wavenumber domain yields peaks in the spectra that correspond to the fracture density of the model, which can be easily observed when the general trend is removed. The peaks in the normalized spectra are not sensitive to the spectrum used to remove the general trend.

However, two important issues in using this method were identified when attempting to resolve the fracture density of .0286-fractures/meter. The spatial resolution of this method is controlled by the spacing of the receivers. For a specified maximum fracture density to be resolved, the receiver spacing must be at least half of that maximum fracture density as governed by the Nyquist criterion.

Another consideration is that the amplitudes of the fluctuations in the .0286-fractures/meter case are much smaller than in the other two cases that were successful. This may be due to the window of the data not capturing enough of the scattered energy responsible for the

interference patterns that lead to the fracture density estimation. In fact, this observation can be somewhat validated by examining the time series for the .0286-fractures/meter case, which show a lack of almost any events within the time window used for this analysis. Instead, this case shows strong scattered energy just below the window used in this analysis. Therefore, the optimal window used for this method may depend on the fracture density and may require additional constraints.

We have focused our more detailed spectral analysis on the time window around the P-wave reflection from the base of the reservoir. However, we have shown that a great deal of energy is scattered and results in events that arrive significantly later than the primary P-wave reflections. To capture information about these scattered events, we use the 2D FFT to generate frequency versus wavenumber plots for each fracture density case. When this method is applied to data in the direction normal to the fractures spectral peaks associated with backscattering from the fractures can be separated. These backscattered spectral peaks have narrow bandwidth and in general have increasing peak frequency as the fracture density increases. In addition, the same spectral peaks are present in the direction parallel to the fractures; however, they arrive with similar move-out trends as the reflections. Therefore, identifying these scattering events in the frequency – wavenumber domain may provide information regarding fracture density as well as the orientation of the fracture zones.

In this paper, we have only investigated the effect of variations in the spacing between discrete fractures. For this model, the effect of fracture stiffness, fracture zone thickness (in this study the fracture zones were set to the grid size of 5 meters), heterogeneous fracture spacing, and reservoir thickness on the scattered wavefield should also be investigated. In addition, we

have only focused on one component of the wavefield. It would be beneficial to look at horizontal components as well in order to investigate the relative strength of P and S wave scattering.

Examining a simple model such as the one presented in this paper allows for many fundamental observations related to scattering from discrete fracture zones. Lessons learned from this effort should be used to develop more complex models that incorporate other fundamental effects in real seismic data. Such complexities include additional layers above the reservoir, intrinsic attenuation, and layer anisotropy.
