AN EFFICIENT AND ROBUST SCALAR AUXILIARY VARIABLE
BASED ALGORITHM FOR DISCRETE GRADIENT SYSTEMS
ARISING FROM OPTIMIZATIONS

XINYU LIU\textsuperscript{\dagger}, JIE SHEN\textsuperscript{\ddagger}, AND XIANGXIONG ZHANG\textsuperscript{\dagger}

Abstract. We propose in this paper a new minimization algorithm based on a slightly modified
version of the scalar auxiliary variable (SAV) approach coupled with a relaxation step and an
adaptive strategy. It enjoys several distinct advantages over popular gradient based methods: (i)
it is unconditionally energy diminishing with a modified energy which is intrinsically related to
the original energy, and thus no parameter tuning is needed for stability; (ii) it allows the use
of large step-sizes which can effectively accelerate the convergence rate. We also present a convergence
analysis for some SAV based algorithms, which include our new algorithm without the relaxation
step as a special case. We apply our new algorithm to several illustrative and benchmark problems
and compare its performance with several popular gradient based methods. The numerical results
indicate that the new algorithm is very robust, and its adaptive version usually converges significantly
faster than those popular gradient decent based methods.

1. Introduction. Minimization plays an important role in many branches of
science and engineering. In particular, how to accelerate the convergence rate of the
minimization process is a central issue in data science and machine learning problems.
We consider in this paper an unconstrained minimization problem
\begin{equation}
\min_{\theta \in \mathbb{R}^N} f(\theta),
\end{equation}
which arises in many applications, including particularly machine learning problems.
For large scale minimization problems, the first order methods such as gradient descent
(GD) and its variants such as stochastic GD [21], Nesterov’s accelerated GD [17], and
the adaptive momentum estimation method [15, 24, 10] are popular choices. We refer
to [19, 18, 23], and the references therein, for more detail on the design and analysis
of the GD method and its various variants.

The vanilla GD method for (1.1) is
\begin{equation}
\theta_{k+1} = \theta_k - \eta_k \nabla f(\theta_k),
\end{equation}
which can also be regarded as a numerical scheme for the gradient flow
\begin{equation}
\theta_t = -\nabla f(\theta),
\end{equation}
with time step $\eta_k$. The gradient flow (1.3) is energy diminishing in the sense that

Obviously, with \( r(t) = 0 \), we introduce a scalar auxiliary variable \( r(t) = \sqrt{g(\theta) + C} \) and expand (1.5) to

\[
\begin{cases}
\theta_k + \mathcal{L}\theta + \nabla g(\theta) = 0, \\
r_k = -\frac{1}{2\sqrt{g(\theta) + C}} (\nabla g(\theta), \theta).
\end{cases}
\]

Obviously, with \( r(0) = \sqrt{g(\theta)|t=0| + C} \), the above system admits a solution \( r(t) = \sqrt{g(\theta) + C} \) with \( \theta \) being the solution of (1.5). The main advantage of the expanded system, which includes an energy evolution equation, is that it allows us to construct simple numerical schemes with modified energy diminishing. For example, the scheme

\[
\begin{cases}
\frac{\theta_{k+1} - \theta_k}{\delta t} + \mathcal{L}\theta_{k+1} + \frac{\nabla g(\theta_k)}{\sqrt{g(\theta_k) + C}} r_{k+1} = 0, \\
\frac{r_{k+1} - r_k}{\delta t} = \left( -\frac{\nabla g(\theta_k)}{2\sqrt{g(\theta_k) + C}}, \frac{\theta_{k+1} - \theta_k}{\delta t} \right)
\end{cases}
\]

can be easily implemented by solving only two linear systems of the form \((I + \delta t\mathcal{L})x = b\) and is unconditionally energy stable with a modified energy [26].

While the scheme (1.7) has been shown to be very effective for gradient flows, it is not particularly suitable for the minimization problem (1.1). Indeed, for any fixed \( \delta t \), assuming \( \theta_k \to \theta^* \) and \( r_k \to r^* \), then \( \frac{r_k}{\delta t} \to \frac{r^*}{\delta t} \), which is usually not equal to 1, and consequently, the first equation of (1.7) leads to

\[
0 = \mathcal{L}\theta^* + \frac{r^*}{\sqrt{g(\theta^*) + C}} \nabla g(\theta^*) = \mathcal{L}\theta^* + \frac{r^*}{\sqrt{g(\theta^*) + C}} (-\mathcal{L}\theta^* + \nabla f(\theta^*)).
\]

If \( \mathcal{L} \neq 0 \), we observe from the above that in general \( \nabla f(\theta^*) \neq 0 \) and thus \( \theta^* \) is not a solution for (1.1). Another complication of this approach is that it is not obvious how
to choose $\mathcal{L}$ such that $g(\theta)$ is bounded from below for all $\theta$. The main goal of this paper is to design suitable SAV based schemes for (1.1), develop their convergence theory, and validate them through extensive numerical experiments.

The rest of the paper is organized as follows. In section 2, we first discuss a suitable SAV algorithm for minimization, introduce its relaxed version (RSAV), and discuss the adaptive rule and choices for the nonnegative operator $\mathcal{L}(\theta)$. Then, we present in section 3 several numerical results to show the performance of the RSAV in different optimization problems. We provide a convergence study in section 4 and some concluding remarks in section 5.

2. A new SAV approach and its relaxed version. We have observed in the last section that the standard SAV approach is not suitable for the minimization problem (1.1). In this section, we propose a different SAV approach and its related version, which are well suited for (1.1).

2.1. A modified SAV approach. We still assume the splitting (1.4) and rewrite (1.3) as

\begin{equation}
\theta_t + \mathcal{L}\theta + \nabla f(\theta) - \mathcal{L}\theta = 0.
\end{equation}

Since $f(\theta)$ in a minimization problem should always be bounded from below, there exists $C > 0$ such that $f(\theta) > -C$ for all $\theta$. We introduce $r(t) = \sqrt{f(\theta) + C}$ and expand (2.1) to

\begin{equation}
\begin{cases}
\theta_t + \mathcal{L}\theta + \frac{\nabla f(\theta)}{\sqrt{f(\theta) + C}} r - \mathcal{L}\theta = 0, \\
r_t = \frac{1}{2\sqrt{f(\theta) + C}} (\nabla f(\theta), \theta_t).
\end{cases}
\end{equation}

Then, a simple SAV scheme to approximate the above is

\begin{equation}
\begin{aligned}
\frac{\theta_{k+1} - \theta_k}{\delta t} + \mathcal{L}\theta_{k+1} + \frac{\nabla f(\theta_k)}{\sqrt{f(\theta_k) + C}} r_{k+1} - \mathcal{L}\theta_k &= 0, \\
r_{k+1} - r_k &= \frac{\nabla f(\theta_k)}{2\sqrt{f(\theta_k) + C}} \frac{\theta_{k+1} - \theta_k}{\delta t}.
\end{aligned}
\end{equation}

Note that if $\theta_k \to \theta^*$ and $r_k \to r^*$, then (2.3) leads to $\nabla f(\theta^*) = 0$, and consequently $\theta^*$ is a solution of (1.1).

The scheme (2.3) leads to a coupled linear system for $(\theta_{k+1}, r_{k+1})$, but it can be implemented explicitly after solving a linear system, as will be shown in section 4.1. Let $A = I + \delta t \mathcal{L}$, and then (2.3) can be equivalently implemented as

\begin{align*}
r_{k+1} &= \frac{1}{1 + \delta t \frac{\nabla f(\theta_k) A^{-1} \nabla f(\theta_k)}} r_k, \\
\theta_{k+1} &= \theta_k - \frac{r_{k+1}}{\sqrt{f(\theta_k) + C}} \delta t A^{-1} \nabla f(\theta_k).
\end{align*}

Moreover, taking the discrete inner product of the first (resp., second) equation in (2.3) with $\theta_{k+1} - \theta_k$ (resp., $2r_{k+1}$) and summing up the results, we obtain the following.

**Theorem 1.** If $\mathcal{L}$ is nonnegative, then for any $\delta t > 0$, the modified energy $r^2$ in the scheme (2.7) is unconditionally diminishing in the sense that

\begin{equation}
r_{k+1}^2 - r_k^2 = - \frac{1}{\delta t} \|\theta_{k+1} - \theta_k\|^2 - (\mathcal{L}(\theta_{k+1} - \theta_k), (\theta_{k+1} - \theta_k)) - (r_{k+1} - r_k)^2.
\end{equation}
The above result shows the key advantage of (2.3): the energy dissipation holds for any $\delta t > 0$ and any splitting with nonnegative $L$.

As we shall demonstrate in numerical tests in section 3, when the cost functional $f(\theta)$ has a suitable splitting, the above algorithm usually converges much faster than the vanilla gradient decent method. When the cost function does not have any obvious quadratic part, we can either choose any suitable nonnegative linear operator $L$ in (1.4) or simply take $L = 0$, which results in a fully explicit method,

\[
\begin{aligned}
\frac{\theta_{k+1} - \theta_k}{\delta t} + \frac{\nabla f(\theta_k)}{\sqrt{f(\theta_k)+C}} r_{k+1} &= 0, \\
r_{k+1} - r_k &= \left( -\frac{\nabla f(\theta_k)}{2\sqrt{f(\theta_k)+C}} \frac{\theta_{k+1} - \theta_k}{\delta t} \right),
\end{aligned}
\tag{2.4}
\]

which we refer to as the SAV GD method. As will be shown in section 4.1, the scheme (2.4) can be decoupled and implemented as

\[
\begin{aligned}
r_{k+1} &= \frac{r_k}{1 + \delta t \frac{(\nabla f(\theta_k), \nabla f(\theta_k))}{2f(\theta_k)+C}}, \\
\theta_{k+1} &= \theta_k - \delta t \frac{r_{k+1}}{\sqrt{f(\theta_k)+C}} \nabla f(\theta_k).
\end{aligned}
\tag{2.5}
\]

Compared with the vanilla GD method (1.2), there are extra computational costs of computing both $f(\theta_k)$ and $(\nabla f(\theta_k), \nabla f(\theta_k))$ in (2.5), but Theorem 1 ensures stability for any $\delta t$. In contrast, $\delta t$ in (1.2) needs to be small enough to ensure stability.

### 2.2. A relaxed version of the modified SAV approach.

While for fixed $\delta t$, the solution of the SAV scheme (2.3) converges to a solution of the minimization problem (1.1), the evolution of $r_{k+1}$ is not directly linked to $\sqrt{f(\theta_{k+1})+C}$, and its value may decrease rapidly to ensure stability when $\| \nabla f(\theta_k) - L \theta_k \|$ becomes large. In this case, the ratio $r_{k+1}/\sqrt{f(\theta_{k+1})+C}$ may deviate significantly from 1, which indicates that $r_{k+1}$ is no longer a good approximation of $\sqrt{f(\theta_{k+1})+C}$, and thus $\theta_{k+1}$ will not be a good approximation of $\theta(t_{k+1})$. For dynamic simulation of gradient flows, a remedy is to monitor the ratio $\sqrt{f(\theta_{k+1})+C}$ and adjust the time step so that it stays close to 1. For the minimization problem (1.1), since we are mainly interested in the steady state solutions of (1.3), it is found in [32] that setting $r_{k+1} = \sqrt{f(\theta_{k+1})+C}$ at each time step is also very effective. More precisely, we can use the following modified SAV scheme:

\[
\begin{aligned}
\frac{\theta_{k+1} - \theta_k}{\delta t} + L \theta_{k+1} + \frac{\nabla f(\theta_k)}{\sqrt{f(\theta_k)+C}} \tilde{r}_{k+1} - L \theta_k &= 0, \\
\frac{\tilde{r}_{k+1} - \tilde{r}_k}{\delta t} &= \left( -\frac{\nabla f(\theta_k)}{2\sqrt{f(\theta_k)+C}} \frac{\theta_{k+1} - \theta_k}{\delta t} \right), \\
\tilde{r}_{k+1} &= \sqrt{f(\theta_{k+1})+C}.
\end{aligned}
\tag{2.6}
\]

However, the above-modified SAV scheme is no longer energy diminishing. Recently, another way to link $r_{k+1}$ with $\sqrt{f(\theta_{k+1})+C}$ while still being energy diminishing is proposed in [30] (see also [14, 29]). When applied to (2.1), the relaxed SAV method takes the following form:

\[
\begin{aligned}
\frac{\theta_{k+1} - \theta_k}{\delta t} + L \theta_{k+1} + \frac{\nabla f(\theta_k)}{\sqrt{f(\theta_k)+C}} \tilde{r}_{k+1} - L \theta_k &= 0, \\
\frac{\tilde{r}_{k+1} - \tilde{r}_k}{\delta t} &= \left( -\frac{\nabla f(\theta_k)}{2\sqrt{f(\theta_k)+C}} \frac{\theta_{k+1} - \theta_k}{\delta t} \right), \\
\tilde{r}_{k+1} &= \xi \tilde{r}_{k+1} + (1 - \xi) \sqrt{f(\theta_{k+1})+C}.
\end{aligned}
\tag{2.7}
\]

Here, the relaxation parameter $\xi$ is a scalar chosen from the set
(2.8) \[ V = \{ \xi \in [0, 1] : (r_{k+1})^2 - (\tilde{r}_{k+1})^2 - (\tilde{r}_{k+1} - r_k)^2 \leq \eta \mathcal{G}(\theta_{k+1}, \theta_k) \}, \]

where \( \mathcal{G}(\theta_{k+1}, \theta_k) = \frac{1}{\eta} ((\theta_{k+1} - \theta_k), A(\theta_{k+1} - \theta_k)) \) with \( A = I + \delta t \mathcal{L} \), and \( \eta \in [0, 1] \) is an artificial parameter with default value \( \eta = 0.99 \). In particular, it is shown in [14] that we can choose

(2.9) \[ \xi = \max \left\{ 0, \frac{-b - \sqrt{b^2 - 4ac}}{2a} \right\}, \]

with the coefficients that

(2.10) \[ a = (\tilde{r}_{k+1} - \sqrt{f(\theta_{k+1}) + C})^2, \]

(2.11) \[ b = 2 (\tilde{r}_{k+1} - \sqrt{f(\theta_{k+1}) + C}) \sqrt{f(\theta_{k+1}) + C}, \]

(2.12) \[ c = f(\theta_{k+1}) + C - (\tilde{r}_{k+1})^2 - (\tilde{r}_{k+1} - r_k)^2 - \eta \mathcal{G}(\theta_{k+1}, \theta_k). \]

Taking the discrete inner product of the first (resp., second) equation in (2.7) with \( \theta_{k+1} - \theta_k \) (resp., \( 2 \tilde{r}_{k+1} \)) and summing up the results, we get

(2.13) \[ \mathcal{G}(\theta_{k+1}, \theta_k) = \frac{1}{\delta t} ( (\theta_{k+1} - \theta_k), A(\theta_{k+1} - \theta_k) ) = -2(\tilde{r}_{k+1} - r_k)\tilde{r}_{k+1}, \]

and then the nonzero choice of \( \xi \) can be rewritten as

\[ \xi = \frac{-b - \sqrt{b^2 - 4ac}}{2a} = \frac{\sqrt{f(\theta_{k+1}) + C} - \sqrt{(\tilde{r}_{k+1})^2 + (\tilde{r}_{k+1} - r_k)^2 + \eta \mathcal{G}(\theta_{k+1}, \theta_k)}}{\sqrt{f(\theta_{k+1}) + C} - \tilde{r}_{k+1}} \]

\[ = \frac{\sqrt{f(\theta_{k+1}) + C} - \sqrt{(1 - \eta)\tilde{r}_{k+1}^2 + \eta r_k^2 + (1 - \eta)(\tilde{r}_{k+1} - r_k)^2}}{\sqrt{f(\theta_{k+1}) + C} - \tilde{r}_{k+1}}. \]

The implementation of (2.7) is summarized in Algorithm 1.

**Theorem 2.** If \( \mathcal{L} \) is nonnegative and linear, then for any \( \delta t > 0 \), the modified energy \( r^2 \) in the scheme (2.7) is unconditionally diminishing in the sense that

\[ r_{k+1}^2 - r_k^2 = -(1 - \eta) \mathcal{G}(\theta_{k+1}, \theta_k) \leq 0. \]

**Proof.** By (2.13), we obtain

\[ \tilde{r}_{k+1}^2 - r_k^2 = -\frac{1}{\delta t} \| \theta_{k+1} - \theta_k \|^2 - \mathcal{L}(\theta_{k+1} - \theta_k), (\theta_{k+1} - \theta_k)) - (\tilde{r}_{k+1} - r_k)^2. \]

Adding \( r_{k+1}^2 - \tilde{r}_{k+1}^2 \) on both sides and noticing

\[ \mathcal{G}(\theta_{k+1}, \theta_k) = \frac{1}{\delta t} \| \theta_{k+1} - \theta_k \|^2 + \mathcal{L}(\theta_{k+1} - \theta_k), (\theta_{k+1} - \theta_k)), \]

we obtain

\[ r_{k+1}^2 - r_k^2 = -\mathcal{G}(\theta_{k+1}, \theta_k) - (\tilde{r}_{k+1} - r_k)^2 + r_{k+1}^2 - \tilde{r}_{k+1}^2, \]

which implies the desired result thanks to (2.8). \( \square \)
Algorithm 1 The basic RSAV scheme.

1: Inputs:
\( \delta t \): step-size,
\( C \): constant to guarantee the positivity of \( f(x) + C \),
\( A = I + \delta t \mathcal{L} \): the linear operator,
\( \theta_0 \): initial parameter vector

2: \( r_0 \leftarrow \sqrt{f(\theta_0) + C} \)

3: for \( k = 0, 1, 2, \ldots, M - 1 \) do

4: \( g_k = \nabla f(\theta_k) \sqrt{f(\theta_k) + C} \)

5: \( \hat{g}_k = A^{-1} g_k \)

6: \( \tilde{r}_{k+1} = \frac{r_k}{1 + \frac{\delta t}{2}(g_k, \hat{g}_k)} \)

7: \( \theta_{k+1} = \theta_k - \delta t \tilde{r}_{k+1} \hat{g}_k \)

8: \( \xi = \frac{\sqrt{f(\theta_{k+1}) + C} - \sqrt{(1 - \eta) \tilde{r}_{k+1}^2 + \eta r_k^2 + (1 - \eta)(\tilde{r}_{k+1} - r_k)^2}}{\sqrt{f(\theta_{k+1}) + C} - r_{k+1}} \)

9: \( \xi = \max\{0, \xi\} \)

10: \( r_{k+1} = \xi \tilde{r}_{k+1} + (1 - \xi) \sqrt{f(\theta_{k+1}) + C} \)

return \( \theta_M \)

2.3. Selection of the operator \( \mathcal{L} \). In the SAV approach for gradient flows [26], it is found that a proper choice of the splitting (1.4), i.e., the choice of the quadratic term \( \frac{1}{2}(\mathcal{L} \theta, \theta) \), can significantly increase the robustness and efficiency of the SAV schemes. For gradient flows coming from materials science or fluid dynamics, there are usually obvious candidates in the free energy. However, for minimization problems, particularly those from machine learning problems, there are usually no obvious quadratic terms in the energy functions. In these cases, we can artificially choose some simple operators. In this paper, we consider two simple operators below, for which the inverse operator \((I + \delta t \mathcal{L})^{-1}\) can be efficiently implemented.

2.3.1. Diagonal matrix. In many optimization problems, an \( l^2 \) regularization term is often added into the loss function to avoid overfitting to the data in training sets, namely,

\[
J(x) = f(x) + \frac{\lambda}{2} \| x \|^2.
\]

In this case, a natural choice is to set \( \mathcal{L} = \lambda I \). More generally, we can use \( \mathcal{L} = D \) with \( D \) being a diagonal matrix with positive entries, e.g., \( D \) can be the diagonal entries of the Hessian of the cost function.

2.3.2. Discrete Laplacian matrix. In some machine learning problems, the discrete Laplacian matrix is used as a smoothing operator which can reduce the variance during the minibatch training process [20]. This corresponds to \( \mathcal{L} = -\sigma \Delta \), where \( \sigma \) is a positive parameter and \( \Delta \) is a discrete Laplacian matrix, and \((I + \delta t \mathcal{L})^{-1}\) can be efficiently inverted by FFT based methods. The acceleration by using discrete Laplacian in classical primal dual algorithms has been also justified in [13].

2.4. An adaptive algorithm based on the RSAV scheme (2.7). Similar to the modified SAV scheme (2.3), the RSAV scheme (2.7) is also unconditionally energy diminishing. A main advantage of unconditionally stable schemes is that one can adaptively adjust the time step size to achieve faster convergence. In particular, we can use
Then, Theorems 1 and 2 still hold with \( \mathscr{L} \) and (2.7) by a linear nonnegative operator \( \mathscr{L} \). Restart the RSAV scheme at the beginning of each minibatch. As solving differential equations \( \theta_k = -\nabla f(\theta) \), \( I_k(r, \theta) \) should be as close to 1 as possible for the sake of the time accuracy. But for a minimization problem, there is no time accuracy issue, and thus we can allow \( I_k(r, \theta) \) to deviate from 1 to achieve faster convergence. However, \( I_k(r, \theta) \) needs to be away from zero to avoid slow convergence, as the SAV and RSAV algorithms may converge much slower than the vanilla GD when the ratio \( I_k(r, \theta) \) becomes too small.

We observe from (2.7) that the true step-size for the gradient \( \nabla f(\theta_k) \) is \( \frac{\tilde{r}_{k+1}}{\sqrt{f(\theta_k)+C}} \delta t \). Thus if the ratio is small, i.e., \( I_k(r, \theta) < \gamma \), the true step-size for the gradient would be too small, resulting in slow convergence. To this end, we present a simple adaptive rule with an adaptive constant \( \rho > 1 \) with default value \( \rho = 1.1 \) described in Algorithm 2.

**Remark 1.** Note that in many applications of neural networks and machine learning, the cost of computing the full batch is generally too high. In these cases, we can adopt the minibatch approach commonly used in stochastic gradient decent and restart the RSAV scheme at the beginning of each minibatch.

**Remark 2.** As a further generalization, we may replace the operator \( \mathcal{L} \) in (2.3) and (2.7) by a linear nonnegative operator \( \mathcal{L}_k \), which may depend on \( \theta_k \) at each step. Then, Theorems 1 and 2 still hold with \( \mathcal{L} \) replaced by \( \mathcal{L}_k \).

**Algorithm 2** The adaptive RSAV scheme.

1. **Inputs:**
   \( \delta t_0 \): initial step-size, \( \delta t_{\text{min}} \): the lower bound of step-size,
   \( C \): constant to guarantee the positivity of \( f(x) + C \),
   \( A = I + \delta t \mathcal{L} \): the linear operator,
   \( \theta_0 \): initial parameter vector,
   \( \rho \): adaptive constant which is greater than 1,
   \( \gamma \): threshold for the indicator \( I(r, \theta) \).
2. \( r_0 \leftarrow \sqrt{f(\theta_0)+C} \): Initialize the SAV,
3. **for** \( k = 0, 1, 2, \ldots, M - 1 \) **do**
4.   **if** \( \frac{r_k}{\sqrt{f(\theta_k)+C}} < \gamma \) and \( \delta t > \delta t_{\text{min}} \) **then**
5.     \( \delta t_{k+1} = \max \left\{ \frac{r_k}{\sqrt{f(\theta_k)+C}} \delta t_k, \delta t_{\text{min}} \right\} \)
6.   **else**
7.     \( \delta t_{k+1} = \rho \delta t_k \)
8. **end if**
9. \( g_k = \nabla f(\theta_k) \sqrt{f(\theta_k)+C} \)
10. \( \tilde{g}_k = A^{-1} g_k \)
11. \( \tilde{r}_{k+1} = \frac{r_k}{1 + \frac{r_k}{\sqrt{f(\theta_k)+C}}} \)
12. \( \theta_{k+1} = \theta_k - \delta t_{k+1} \tilde{r}_{k+1} \tilde{g}_k \)
13. \( \xi = \sqrt{f(\theta_{k+1})+C - (1-\eta)\tilde{r}_{k+1}^2 + (1-\eta)\tilde{r}_{k+1}^2 + (1-\eta)\tilde{r}_{k+1}^2} \)
14. \( \xi = \max \{0, \xi\} \)
15. \( r_{k+1} = \xi \tilde{r}_{k+1} + (1 - \xi) \sqrt{f(\theta_{k+1})+C} \)
16. **return** \( \theta_M \)
3. Numerical results. We present in this section several illustrative numerical experiments by using our RSAV approach and compare it with popular gradient based approaches.

In order to present a fair comparison to GD, we consider a composite gradient method. By abuse of notation, we shall refer to GD with $\mathcal{L}$ as the following method for the splitting (1.4):

$$\theta_{k+1} + \delta t \mathcal{L} \theta_{k+1} = \theta_k + \delta t (\mathcal{L} \theta_k - \nabla f(\theta_k)),$$

which is equivalent to

$$\theta_{k+1} = \theta_k - \delta t (I + \delta t \mathcal{L})^{-1} \nabla f(\theta_k).$$

The scheme (3.1) can also be regarded as the forward-backward splitting scheme

$$\theta_{k+1} = \theta_k - \delta t \nabla F(\theta_k) - \delta t \nabla G(\theta_{k+1})$$

for minimizing a composite function $F(\theta) + G(\theta)$ with $F(\theta) = f(\theta) - \frac{1}{2} \theta^T \mathcal{L} \theta$ and $G(\theta) = \frac{1}{2} \theta^T \mathcal{L} \theta$.

Note that the scheme (3.1) reduces to the vanilla GD (1.2) if setting $\mathcal{L} = 0$, and (3.1) reduces to the vanilla GD (1.2) with step-size $\frac{\delta t}{1 + \delta t}$ if setting $\mathcal{L} = I$. Therefore, we do not consider GD with $\mathcal{L} = I$, and we compare the adaptive RSAV in Algorithm 2 to the following algorithms:

1. GD with $\mathcal{L} = 0$, which is the vanilla GD (1.2),
2. GD with $\mathcal{L} = -\sigma \Delta$ with discrete Laplacian $\Delta$, which is similar to the Laplacian smoothing GD [20],
3. ADAM [15],
4. Nesterov accelerated GD (NAG) [16].

Unless specified otherwise, we use ADAM and NAG with the default parameter settings as in [22]: NAG with $\gamma = 0.9$ and ADAM with $\beta_1 = 0.9, \beta_2 = 0.999, \varepsilon = 10^{-8}$.

3.1. A quadratic cost function. We start with a quadratic loss function from [20]:

$$f(\theta_1, \theta_2, \ldots, \theta_{100}) = \sum_{i=1}^{50} \theta_{2i-1}^2 + \sum_{i=1}^{50} \frac{1}{100} \theta_{2i}^2.$$

For this simple function, we take either $\mathcal{L} = 0$ or $\mathcal{L} = D$, where the diagonal matrix $D$ is chosen to be the Hessian $\nabla^2 f(\theta)$.

To demonstrate the unconditional stability of SAV based approaches, in Table 1 and Figure 1 we show the results of different initial step-sizes $\delta t$ for the vanilla GD, i.e., GD with $\mathcal{L} = 0$, as well as GD with $\mathcal{L} = D$. We observe that the vanilla GD blows up for the constant step-size $\delta t = 1$, while the adaptive RSAV works quite well.

Next we consider the gradient perturbed by a Gaussian noise

$$\nabla \epsilon f(x) := \nabla f(x) + \epsilon \mathcal{N}(0, I),$$

where $\epsilon$ controls the noise level, and $\mathcal{N}(0, I)$ is the Gaussian noise vector with zero mean and unit variance in each coordinate. The comparison is given in Table 2 and Figure 2, where $\mathcal{L} = 0$ is used for both GD and adaptive RSAV. We observe that the adaptive RSAV converges much faster than GD. The fast convergence of adaptive RSAV is partly due to the indicator $I_k(r, \theta)$, which can give a proper step-size. Especially in the noisy case, the true step-size is given at a proper level to reach a better convergence than GD and reduce the oscillation in the loss curves.

**Table 2**

Loss curves for GD and adaptive RSAV with different noise levels $\epsilon$. The learning rate (lr) refers to the step-size $\delta t$ for GD and the initial step-size $\delta t$ in the adaptive RSAV.

**Fig. 2.** Loss curves for GD and adaptive RSAV with different noise levels. The learning rate (lr) refers to the step-size $\delta t$ for GD and the initial step-size $\delta t$ in the adaptive RSAV.
To find the valley is trivial, but to converge to the global minimum it has a global minimum at $(x, y) = (0, 0)$. The function has a global minimum at $(x, y) = (0, 0)$. In this example, we compare the adaptive RSAV with popular optimization methods ADAM and NAG with their default parameter settings as in [22]: NAG with $\gamma = 0.9$ and ADAM with $\beta_1 = 0.9, \beta_2 = 0.999, \varepsilon = 10^{-8}$. We shall keep using these default settings in all following experiments.

We plot in the left of Figure 3 the convergence curves of different methods and observe that the RSAV converges much faster than ADAM with the same initial step-size. We also plot in the right of Figure 3 the paths toward the minimum by different methods. We observe that RSAV enjoys a fast convergence if using a large initial step-size $\delta t$.

### 3.3. Rosenbrock function.

This is a benchmark problem for the optimization of nonconvex functions. We first consider the two-dimensional (2D) case with

$$f(x, y) = (a - x)^2 + b(y - x^2)^2;$$

it has a global minimum at $(x, y) = (a, a^2)$, which is inside a long narrow, parabolic shaped flag valley. To find the valley is trivial, but to converge to the global minimum is usually difficult.

Fig. 4. 2D Rosenbrock problem. Left: Convergence curves. Right: Paths with 1,000 iterations in the $(\theta_1, \theta_2)$ domain.

We set $a = 1$ and $b = 100$ in the following experiments and other parameters the same as in [20] and start with the initial point with coordinate $(-3, -4)$. In Table 4, we observe that a large step-size can lead to blow-up for other methods except for RSAV. Thus in Figure 4, we only show the results with the largest suitable step-sizes for other algorithms. For adaptive RSAV, we just use the same initial step-size as ADAM. This example reveals the benefits of the modified energy decreasing property of the RSAV. Although ADAM can get close to the global minimum at first, it still goes to the wrong direction caused by the momentum and eventually goes back after wasting many iterations. Only RSAV converges to the global minimum directly with the guide of decreasing (modified) energy.

Next, we consider the high-dimensional cases with

\[
 f(x) = \sum_{i=1}^{n} (a - \theta_i)^2 + b \sum_{i=1}^{n-1} (\theta_{i+1} - \theta_i^2)^2, \tag{3.6}
\]

with the global minimum $f(x^*) = 0$ at $x^* = (a, a^2, a, a^2, \ldots, a, a^2)$. We take $a = 1$ and $b = 100$ and the initial point $(0, \ldots, 0)$. The results with the dimension equal to 10, 100, and 1000 are shown in Figure 5. We observe similar convergence behavior for all cases as in the 2D case.

Remark 3. If we compare the adaptive RSAV with Nesterov accelerated gradient decent, the results are still quite good, especially when the dimension is 1000. Thanks to the adaptive scheme, the performance of RSAV in this problem is independent of the dimension.
3.4. Phase retrieval. The phase retrieval problem [5] can be formulated as
\[
\min_{z \in \mathbb{C}^N} f(z) := \frac{1}{2} \| \mathbf{A}(z^*z) - b \|^2,
\]
where $z^* \in \mathbb{C}^{1 \times N}$ is the conjugate transpose of $z$, $b \in \mathbb{R}^M$ and $\mathbf{A} : \mathbb{C}^{N \times N} \rightarrow \mathbb{R}^M$ is a linear operator. For the real-valued function $f(z)$ with complex variable $z := a + ib$, where $i$ is the imaginary unit and $a, b \in \mathbb{R}$ are real and imaginary parts of $z$, we can define the Fréchet derivative induced by the natural choice of real inner product for $\mathbb{C}^N$ as the following [31]:
\[
\nabla f(z) := \frac{\partial f(z)}{a} + i \frac{\partial f(z)}{b} = 2A^*(A(z^*z - b))z,
\]
where $A^*$ is the adjoint operator of $A$. Then the vanilla GD algorithm for $\min_{z \in \mathbb{C}^N} f(z)$ can be defined as in (1.2) using $\nabla f(z)$ above. The GD method with a suitable step sizing rule is also referred to as the Wirtinger flow [6].

In particular, $f(z)$ is a nonconvex quartic polynomial function of $z$. For the theoretical convergence of minimizing such a nonconvex function, with a spectral initialization, i.e., $z_0$ being the leading eigenvector of $A^*(b)$, the convergence of Wirtinger flow with high probability can be proven for a very special class of phase retrieval problems [6, 4]. For solving phase retrieval with random initial guess, the convergence for minimizing a smoothed amplitude flow based model was proven in [3]. In terms of practical performance with only random initialization, state-of-the-art algorithms such as the Riemannian Limited-memory Broyden–Fletcher–Goldfarb–Shanno method (LBFGS) method could be much more efficient than GD algorithms [6].

We emphasize that we only use such phase retrieval problems as a testing example to validate the performance of the RSAV method. So we test the algorithms with a random initialization.

We compare vanilla GD, adaptive RSAV with $\mathcal{L} = 0$, and steepest descent (SD) [8, 2]. The SD method is to use the optimal step-size in (1.2), and it is possible to compute such an optimal step-size for a polynomial cost function. We test the performance of the RSAV algorithm on the following phase retrieval problem. Let $\mathcal{M}_i \in \mathbb{C}^N$ be independent and identically distributed Gaussian and $\circ$ denote the entrywise product. Let $\mathcal{F}$ denote the Fourier transform. The linear operator $A$ is defined by assigning $||\mathcal{F}(\mathcal{M}_i \circ \mathbf{z})||^2$ to $b$, e.g., $\frac{1}{N} = m$. We consider the test case for the true solution $z_*$ being an image of size $n \times n$ with $n = 256$. So the size of unknown is $N = n^2 = 256^2$. We consider two test cases:

![Fig. 5. Loss of Rosenbrock function with dimension n.](image-url)
(a) GD. (b) adaptive RSAV. (c) SD.

Fig. 6. Results after 20,000 iterations for a phase retrieval problem with $z_\ast$ being a $256 \times 256$ real image of camera man, $m = 6$ Gaussian random masks and a random initial guess. The vanilla GD uses the nearly largest stable constant step-size $\delta t = 0.5$.

1. The true minimizer $z_\ast$ is a real image of camera man with size $256 \times 256$ as shown in Figure 6, $m = 6$ Gaussian random masks and a random initial guess.
2. The true minimizer $z_\ast$ is a complex image of golden ball with size $256 \times 256$ (see [12] for details), $m = 10$ Gaussian random masks and a random initial condition.

See Figure 7 for the comparison of the performance of gradient based algorithms. For the vanilla GD, we use the nearly largest stable constant step-size $\delta t = 0.5$. In Figure 8, we list a comparison of the step-size $\delta_k$ in the adaptive RSAV method with the optimal step-size in the SD method. We can see the performance of adaptive RSAV has the closest performance to the SD. For the real image case, SD converged after 10,000 iterations and RSAV converged after 20,000 iterations. However, to compute the optimal step-size in the SD, at least two more evaluations of $\mathcal{A}$ are needed, thus are quite expensive. More importantly, for a general cost function, it is difficult to find the optimal step-size. See section 4.4 for an analysis of the step-size in the explicit SAV GD with restarting $r_k$ every iteration for quadratic functions.

3.5. Recommendation system. Consider applying the optimization scheme to train a recommendation system based on a matrix factorization model. Given a rate matrix $R \in \mathbb{R}^{m \times n}$, where $m$ is the number of users and $n$ is the number of items,
the model learns the user embedding matrix \( X \in \mathbb{R}^{m \times d} \) and item embedding matrix \( Y \in \mathbb{R}^{n \times d} \) such that the product \( XY^T \) is a good approximation for \( R \). Here, \( d \) is the embedding dimension and usually much smaller than \( m \) and \( n \). Denote the user and item matrix by \( X = [X_1, \ldots, X_u, \ldots, X_m]^T \) and \( Y = [Y_1, \ldots, Y_i, \ldots, Y_n]^T \), and we have the loss function as

\[
(3.7) \quad f(X, Y) = \frac{1}{N_\kappa} \sum_{(u, i) \in \kappa} (R_{u,i} - X_u Y_i^T)^2 + \lambda_u \sum_u \|X_u\|^2 + \lambda_i \sum_i \|Y_i\|^2,
\]

where \( \kappa \) is the training set for the \((u, i)\) pairs for which \( R_{u,i} \) is known, \( N_\kappa \) is the number of training data, and \( \lambda_u \) and \( \lambda_i \) are the penalty parameters for embedding matrix. We train the model with the MovieLens 100K dataset [11], which contains 100,000 ratings \((1-5)\) from 943 users on 1682 movies. There is an 80\% data split as the training data and the rest date are used for the testing data, e.g., the training data set \( \kappa \) has size 80,000. All algorithms use the minibatch gradient with batch size 80. For \( l_2 \) regularization, we set \( \lambda_u = \lambda_i = 10^{-4} \). For the linear operator \( \mathcal{L} = \lambda I - \sigma \Delta \) in GD and RSAV, we let \( \lambda = 10^{-4} \) and \( \sigma = 0.1 \). In Figure 9, for the training step, we run 10,000 iterations for the minibatch gradient based methods with batch size 80, which is equal to 10 epochs. The result on the test data is shown in Table 5. We can see that RSAV performs well in the training step, though its testing result is not the best, which suggests issues of overfitting during the training step. This is more or less a modelling issue, rather than the optimization issue.

4. Convergence study for some SAV based algorithms. In this section, we consider a more general version of the SAV scheme based on the following expanded system:

\[
(4.1) \quad \begin{align*}
\theta_t &= - \left( \frac{r}{|f(\theta) + C|^q} \nabla f(\theta) + \mathcal{L} \theta - \mathcal{L} \theta \right), \\
r_t &= q[f(\theta) + C]^{q-1}(\nabla f(\theta), \theta_t),
\end{align*}
\]

where \( r(t) = |f(\theta) + C|^q \) and \( q \in (0, 1) \). Note that (2.2) is a special case of the above formulation with \( q = \frac{1}{2} \). Similar to (2.3), we can construct a SAV scheme for (4.1) as follows:
After a simple Gaussian elimination, we obtain an explicit update formula for (4.2):

\[
\begin{align*}
\frac{\theta_{k+1} - \theta_k}{\delta t} &= -\left( \frac{r_{k+1}}{f(\theta_k) + C}\right) \nabla f(\theta_k) + \mathcal{L}(\theta_{k+1} - \theta_k), \\
\frac{r_{k+1} - r_k}{\delta t} &= q[f(\theta_k) + C]q^{-1}(\nabla f(\theta_k), \theta_{k+1} - \theta_k).
\end{align*}
\]

### 4.1. Interpretation of the SAV method as a line search method.

Let \( A = (I + \delta t \mathcal{L}) \). The system (4.2) can be rewritten as

\[
\begin{bmatrix}
A \\
-q[f(\theta_k) + C]q^{-1}\nabla f(\theta_k)
\end{bmatrix}
\begin{bmatrix}
\delta t \frac{\nabla f(\theta_k)}{f(\theta_k) + C} \\
r_{k+1}
\end{bmatrix}
= \begin{bmatrix}
\theta_{k+1} \\
[\theta_k - \theta_{k+1}]
\end{bmatrix} = \begin{bmatrix}
A\theta_k \\
r_k - q[f(\theta_k) + C]q^{-1}(\nabla f(\theta_k), \theta_k)
\end{bmatrix}.
\]

After a simple Gaussian elimination, we obtain an explicit update formula for (4.2):

\[
\begin{align*}
r_{k+1} &= \frac{1}{1 + \delta t q[f(\theta_k) + A^{-1}\nabla f(\theta_k)]} r_k, \\
\theta_{k+1} &= \theta_k + \frac{r_{k+1}}{f(\theta_k) + C} \delta t A^{-1} \nabla f(\theta_k).
\end{align*}
\]

Notice that the scheme above can be regarded as a line search method:

\[
\begin{align*}
\theta_{k+1} &= \theta_k + \alpha_k P_k, \\
P_k &= -A^{-1} \nabla f(\theta_k), \\
\alpha_k &= \frac{\delta t}{1 + \delta t q[f(\theta_k) + A^{-1}\nabla f(\theta_k)]} \frac{r_k}{f(\theta_k) + C} > 0.
\end{align*}
\]

with a search direction \( P_k \) and step-size \( \alpha_k \).
The step-size \( \alpha_k \) is guaranteed to be positive. On the other hand, it is difficult to establish any a priori control of \( \alpha_k \), and in practice \( \alpha_k \) could become very small if \( r_k \) becomes very small. To avoid small \( r_k \), we consider a special version of the SAV method by redefining \( r_k = [f(\theta_k) + C]^q \), and then we have

\[
\alpha_k = \frac{\delta t}{1 + \delta t q \frac{\nabla f(\theta_k) A^{-1} \nabla f(\theta_k)}{f(\theta_k) + C}}.
\]

In this case, we can view \( q \) as a parameter, and the SAV method with \( r_k = [f(\theta_k) + C]^q \) at every iteration becomes the following line search method,

\[
\begin{align*}
\theta_{k+1} &= \theta_k + \alpha_k P_k, \\
P_k &= -A^{-1} \nabla f(\theta_k), \\
\alpha_k &= \frac{\delta t}{1 + \delta t q \frac{\nabla f(\theta_k) A^{-1} \nabla f(\theta_k)}{f(\theta_k) + C}},
\end{align*}
\]

which is equivalent to

\[
\begin{align*}
r_k &= [f(\theta_k) + C]^q, \\
\frac{\theta_{k+1} - \theta_k}{\delta t} &= -\left( \frac{r_{k+1}}{f(\theta_k) + C} \right)^q \nabla f(\theta_k) + \mathcal{L}(\theta_{k+1} - \theta_k), \\
\frac{f_k - r_k}{\delta t} &= q[f(\theta_k) + C]^q - (\theta_{k+1} - \theta_k).
\end{align*}
\]

In particular, for any \( \mathcal{L} \geq 0 \), \( A^{-1} \) is always positive definite, and thus the search direction \( P_k = -A^{-1} \nabla f(\theta_k) \) is always a descent direction, i.e., \( -\nabla f^T(\theta_k) P_k = \nabla f(\theta_k)^T A^{-1} \nabla f(\theta_k) > 0 \). The Wolfe condition [27] for the line search method (4.4) is as follows: there exists \( 0 < c_1 < c_2 < 1 \) such that

\[
\begin{align*}
f(\theta_k + \alpha_k P_k) &\leq f(\theta_k) + c_1 \alpha_k \nabla f(\theta_k)^T P_k, \\
\nabla f(\theta_k + \alpha_k P_k)^T P_k &\geq c_2 \nabla f(\theta_k)^T P_k.
\end{align*}
\]

We recall first the following result [19].

**Theorem 3.** Assume \( f(\theta) \in C^1 \) and \( f(\theta) \) is bounded from below. For any descent direction \( P_k \), there exist intervals of step lengths satisfying the Wolfe condition.

Notice that \( \alpha(\delta t, q) = \frac{\delta t}{1 + \delta t q \frac{\nabla f(\theta_k) A^{-1} \nabla f(\theta_k)}{f(\theta_k) + C}} \) is an increasing function of \( \delta t \) and an decreasing function of \( q \), and thus there exists \( \delta t \) and \( q \) such that \( \alpha_k = \frac{\delta t}{1 + \delta t q \frac{\nabla f(\theta_k) A^{-1} \nabla f(\theta_k)}{f(\theta_k) + C}} \) satisfies the Wolfe conditions (4.6).

We recall another result [19].

**Theorem 4.** Assume \( f(\theta) \in C^1 \), \( f(\theta) \) is bounded from below and \( \nabla f(\theta) \) is Lipschitz continuous. Let \( \cos \phi_k = \frac{-\nabla f(\theta_k)^T P_k}{\|\nabla f(\theta_k)\| \|P_k\|} \). If \( P_k \) is a descent direction and \( \alpha_k \) satisfies the Wolfe conditions, then the iteration \( \theta_{k+1} = \theta_k + \alpha_k P_k \) satisfies

\[
\sum_{k \geq 0} \cos^2 \phi_k \|\nabla f(\theta_k)\|^2 < \infty.
\]

Let \( \lambda_{\min}(A) \) and \( \lambda_{\max}(A) \) be the smallest and largest eigenvalues of the real symmetric positive definite matrix \( A \), and then by the Courant–Fischer–Weyl minmax principle [7] and the spectral norm \( \|A\| = \lambda_{\max}(A) \), we have

\[
\frac{P_k^T A P_k}{\|P_k\|^2} \geq \lambda_{\min}(A), \quad \|A P_k\| \leq \|A\| \|P_k\| = \lambda_{\max}(A) \|P_k\|,
\]

and thus
Therefore, the uniform lower bound on \( \cos \phi_k \) and (4.7) implies that \( \| \nabla f(\theta_k) \| \to 0 \).

Thus the convergence of the SAV method (4.4) is ensured if using a line search to find \( \delta t, q \) such that \( \alpha_k \) satisfies the Wolfe condition (4.6). We observe that the above algorithm involves computing \( A^{-1} \nabla f(\theta_k) \) and the evaluation of \( f(\theta_k) \) and \( f(\theta_{k+1}) \).

**Remark 4.** In practice, one can use backtracking line search on \( \alpha_k \) to ensure that the Wolfe conditions are satisfied. This in general does not seem advantageous over a simple backtracking line search on \( \alpha \). However, for the SAV GD method (2.4), i.e., \( A = I \), our numerical observation is that the SAV scheme is often more efficient than the backtracking line search on \( \alpha \). With \( A = I \), the scheme (4.4) reduces to the following SAV GD method with two parameters \( \delta t > 0 \) and \( q_k > 0 \):

\[
\begin{align*}
\theta_{k+1} &= \theta_k - \alpha_k \nabla f(\theta_k), \\
\alpha_k &= \frac{\delta t}{1 + \delta t q_k \| \nabla f(\theta_k) \|^2}
\end{align*}
\]

### 4.2. Standard convergence results.

We recall that if \( \alpha_k \) in the line search method, (4.4) satisfies the Goldstein–Armijo rule [1, 9]: there exists \( 0 < c_1 < c_2 < 1 \) such that

\[
f(\theta_k) - c_2 \alpha_k \| \nabla f(\theta_k) \|^2 \leq f(\theta_k - \alpha_k \nabla f(\theta_k)) - f(\theta_k) - c_1 \alpha_k \| \nabla f(\theta_k) \|^2,
\]

and then it is shown (cf. Theorem 2.1.14 in [17]) that \( \| \nabla f(\theta_k) \| \to 0 \).

Theorem 2.1.14 in [17] can be easily adapted to prove the following result for the line search method (4.4).

**Theorem 5.** Assume that \( f(\theta) \) is convex and \( \nabla f(\theta) \) is Lipshitz continuous with the Lipshitz constant \( L \), i.e., \( \| \nabla f(y) - \nabla f(x) \| \leq L \| x - y \| \). If \( \nabla f(\theta_*) = 0 \) and \( \alpha_k \in (0, \frac{2}{L}) \), then

\[
\| \theta_{k+1} - \theta_* \|^2 \leq \| \theta_k - \theta_* \|^2 - \alpha_k \left( \frac{2}{L} - \alpha_k \right) \| \nabla f(\theta_k) \|^2
\]

and

\[
f(\theta_k) - f(\theta_*) \leq \frac{1}{[f(\theta_0) - f(\theta_*)]^{-1} + \| \theta_0 - \theta_* \|^{-2} \sum_k \alpha_k (1 - \frac{L}{2\alpha_k})}.
\]

So for convergence, we need \( \sum_{k=0}^{\infty} \alpha_k (1 - \frac{L}{2\alpha_k}) = +\infty \), which can be ensured if \( \alpha_k \in [a, b] \in (0, \frac{2}{L}) \) for constant bounds \( a > 0 \) and \( b < \frac{2}{L} \). Also, \( \alpha_k < \frac{2}{L} \) will ensure \( f(\theta_{k+1}) < f(\theta_k) \).

### 4.3. Decreasing step-sizes for the SAV GD method.

We derive from (4.8) that

\[
\alpha_k = \frac{\delta t}{1 + \delta t q_k \| \nabla f(\theta_k) \|^2} = \frac{1}{1/\delta t + q_k \| \nabla f(\theta_k) \|^2} \leq \min \left\{ \frac{\delta t}{q_k \| \nabla f(\theta_k) \|^2}, f(\theta_k) \right\}.
\]

For fixed \( \delta t \), the above is often sufficient to ensure \( f(\theta_{k+1}) < f(\theta_k) \) when \( \theta_k \) is far away from the minimizer. It can be understood as follows.

\[
\cos \phi_k = \frac{P_k^T AP_k}{\|AP_k\| \|P_k\|} = \frac{P_k^T AP_k \|P_k\|}{\|P_k\|^2 \|AP_k\|} \geq \frac{\lambda_{\min}(A)}{\lambda_{\max}(A)}.
\]
Hence, \( q \) and \( \delta t < \frac{2}{4m^2} \) is not easier than finding \( f \) and \( \| \theta - \theta_* \| \). Finally, \( m > \| \theta - \theta_* \| \), let \( m \equiv \frac{\| \theta - \theta_* \|}{\| \theta - \theta_* \| \| \theta - \theta_* \|} \), \( \| \theta - \theta_* \| \) be the minimizer and assume \( f(\theta_*) = 0 \). Then the following are sufficient conditions to ensure \( \alpha_k < \frac{1}{2} \) for the SAV GD method with two parameters (4.8):

1. For any \( \delta t > 0 \), \( q_k > \frac{L^2}{4m^2} \).
2. Let \( \delta t \equiv a \frac{t^2}{4m^2} \), where \( a > 0 \), \( q_k > \frac{a-1}{a} \frac{t^2}{4m^2} \).

Remark 5. The first sufficient condition implies that \( \alpha_k = \frac{\| \delta t \| \| \nabla f(\theta) \|}{1 + \delta k \| \nabla f(\theta_*) \|} \) will be a decreasing step-size for any \( \delta t \) if \( q_k \equiv q > \frac{L^2}{4m^2} \). Of course, finding \( \frac{1}{q} < \frac{4m^2}{L^2} \) in general is not easier than finding \( \delta t < \frac{2}{L} \). But if \( 2m^2 > L \), then \( \frac{4m^2}{L^2} > \frac{2}{L} \) implies \( \frac{1}{q} < \frac{4m^2}{L^2} \) is easier to achieve.

Remark 6. As an example of the second sufficient condition, if we pick \( q_k \equiv q = \frac{1}{2} \) and \( a = 2 \), then \( \frac{1}{2} > \frac{1}{2} \frac{L^2}{4m^2} \Leftrightarrow L < 2m \) is sufficient to ensure the SAV GD method with \( q_k \equiv q = \frac{1}{2} \) is decreasing with \( \delta t = \frac{1}{2} \), instead of \( \delta t < \frac{2}{L} \) in (1.2).

Proof. First, by the strong convexity and Lipschitz continuity, we have
\[
\begin{align*}
    f(x) &\geq f(y) + \langle \nabla f(y), x - y \rangle + \frac{m}{2} \| x - y \|^2, \\
    f(x) &\leq f(y) + \langle \nabla f(y), x - y \rangle + \frac{L}{2} \| x - y \|^2.
\end{align*}
\]
Since \( \theta_* \) is the minimizer, \( \nabla f(\theta_*) = 0 \). For any \( \theta \), we have
\[
(\nabla f(\theta) - \nabla f(\theta_*), \theta - \theta_*) \geq m \| \theta - \theta_* \|^2 \Rightarrow (\nabla f(\theta), \theta - \theta_*) \geq m \| \theta - \theta_* \|^2
\]
\[
\Rightarrow m \| \nabla f(\theta) \| = \frac{(\nabla f(\theta), \theta - \theta_*)}{\| \theta - \theta_* \| \| \nabla f(\theta) \|} \leq 1 \Rightarrow \| \nabla f(\theta) \| \geq m \| \theta - \theta_* \|. 
\]
Hence,
\[
m \| \theta - \theta_* \| \leq \| \nabla f(\theta) \| \leq L \| \theta - \theta_* \|
\]
and
\[
\frac{m}{2} \| \theta - \theta_* \|^2 \leq f(\theta) - f(\theta_*) \leq \frac{L}{2} \| \theta - \theta_* \|^2.
\]
With strong convexity \( m > 0 \), we have
\[
\frac{2m^2}{L} \leq \frac{\| \nabla f(\theta) \|^2}{f(\theta) - f(\theta_*)} \leq \frac{2L^2}{m}
\]
and thus
\[
\frac{2m^2}{L} \leq \frac{\| \nabla f(\theta) \|^2}{f(\theta)} \leq \frac{2L^2}{m}.
\]
Finally,
\[
\frac{f(\theta_*)}{q_k \| \nabla f(\theta_*) \|^2} < \frac{2}{L} \Leftrightarrow \frac{1}{q_k} < \frac{\| \nabla f(\theta_*) \|^2}{f(\theta_*)} \frac{2}{L} \Leftrightarrow \frac{1}{q_k} < \frac{4m^2}{L^2}.
\]
Remark 7. In general, if \( f(\theta) \) is only convex but not strongly convex, i.e., \( m = 0 \), and \( f(\theta) + C > 0 \), then we only have
\[
\frac{\| \nabla f(\theta) \|^2}{f(\theta) + C} \leq \frac{L^2 \| \theta - \theta_* \|^2}{f(\theta_*) + C}.
\]
This gives a lower bound control on step-size:

\[
\alpha_k = \frac{\delta t}{1 + \delta t q_k \frac{\| \nabla f(\theta_k) \|_2}{f(\theta_k) + C}} \geq \frac{\delta t}{1 + q_k \delta t \frac{2 \| \theta_k - \theta_{k-1} \|_2}{f(\theta_k) + C}}.
\]

In this case, we can set \( q_k \equiv q \) and do back tracking on \( \delta t \) for \( \alpha_k \) to satisfy the convergence condition or Goldstein–Armijo rule.

4.4. The step-size for quadratic functions. To see why the step-size \( \alpha_k = \frac{\delta t}{1 + \delta t q_k \frac{\| \nabla f(\theta_k) \|_2}{f(\theta_k) + C}} \) could be a good step-size to use, at least for a quadratic cost function, consider a cost function \( f(\theta) = \frac{1}{2} \| A\theta - b \|_2^2 \) with a square and positive definite matrix \( A > 0 \). The SD algorithm can be written as

\[
\theta_{k+1} = \theta_k - \beta_k \nabla f(\theta_k), \quad \beta_k = \frac{\| A^T (A\theta_k - b) \|_2^2}{[A^T (A\theta_k - b)]^T A^T A [A^T (A\theta_k - b)].}
\]

The method (4.8) with \( C = 0 \) is

\[
\theta_{k+1} = \theta_k - \alpha_k \nabla f(\theta_k), \quad \alpha_k = \frac{1}{q_k \delta t + \frac{\| A^T (A\theta_k - b) \|_2^2}{f(A\theta_k - b)^T (A\theta_k - b)}}.
\]

Then for a very large \( \delta t k \) and \( q_k \equiv \frac{1}{2} \), we have

\[
\alpha_k \approx \frac{(A\theta_k - b)^T (A\theta_k - b)}{(A\theta_k - b)^T A A^T (A\theta_k - b)}, \quad \beta_k = \frac{(A\theta_k - b)^T A A^T (A\theta_k - b)}{(A\theta_k - b)^T A A^T A (A\theta_k - b)}.
\]

Let \( \lambda_i \) be orthonormal eigenvectors of \( A \) with eigenvalues of \( \lambda_i \). Since \( v_i \) form a basis for \( R^n \), let \( A\theta_k - b = r = \sum_i r_i v_i \). Let \( z = A^T (A\theta_k - b) \), and then \( z = A^T \sum_i r_i v_i = \sum_i r_i \lambda_i v_i \) and \( Az = \sum_i r_i \lambda_i^2 v_i \). We get

\[
\alpha_k \approx \frac{r^T r}{r^T A A^T r} = \frac{r^T r}{z^T z} = \frac{[\sum_i r_i v_i]^T [\sum_i r_i v_i]}{[\sum_i r_i \lambda_i v_i]^T [\sum_i r_i \lambda_i v_i]} = \frac{\sum_i r_i^2}{\sum_i \lambda_i^2 r_i^2}, \quad \beta_k = \frac{[\sum_i \lambda_i^2 r_i^2]}{[\sum_i \lambda_i^2 r_i^2] A^T (Az)} = \frac{[\sum_i \lambda_i^2 r_i^2]}{[\sum_i \lambda_i^2 r_i^2] A^T (Az)}.
\]

We can see that \( \alpha_k \) is very similar to the optimal step-size \( \beta_k \) but not the same. In practice, a random initial guess \( \theta_0 \) usually makes \( \alpha_k \) a descent step-size in the first few or many iterations for \( \delta t k \equiv 1 \) and \( q_k \equiv q = \frac{1}{2} \).

5. Concluding remarks. We proposed in this paper a new minimization algorithm inspired by the scalar auxiliary variable (SAV) approach for gradient flows. Since the direct application of the SAV approach to minimization problems may converge to wrong solutions, we developed a modified version of the SAV approach coupled with a relaxation step and an adaptive strategy. The new algorithm enjoys several distinct advantages, including unconditionally energy diminishing with a modified energy, and empirical better performance than many first order methods. In particular, it overcomes the difficulty in selecting proper step-sizes associated with the usual gradient based algorithms. The energy diminishing property ensures the convergence, and the relaxation step, built on a connection between the decreasing modified energy and the original energy, helps to accelerate the convergence.
We also presented a convergence analysis for some SAV based algorithms which include the new algorithm without the relaxation step as a special case. Numerical results for several illustrative and benchmark problems indicate that the new algorithm is very robust and usually converges significantly faster than those popular gradient decent based methods.

While we only considered a basic version of the SAV based approach which already showed its promise, it is clear that this approach can be combined with other techniques of acceleration and generalization to the gradient decent methods. How to further improve the robustness and accelerate the convergence rate of the SAV based approach will be the subject of a future study.
